Tribute

GuangAn, the native city of Chinese Paramount Leader Deng Xiaoping $(\mbox{$\mathbb{M}$}\mbox{$\mathbb{N}$}\mbox{$\mathbb{N}$})$, is what this Third Generation Tuning Package is named after.

GuangAn 广安

Package for Tuning (3st Generation)

24/06/2023

Background

The purpose of this package is to provide a sophisticated framework for Divide and Conquer tuning. The Criteria of Third Generation Tuning is to be able to work on bounded semi-continuous fields.

The package takes in X and y data for train, validate and test as DataFrame, as well as a dictionary of (hyperparameters bounds-> string: hyperparameter lower/upper bounds as a list, or hyperparameter choices of ordinal/nominal hyperparameter values as a set).

Algorithm Description

GuangAn begins by tuning the vertices/corner combinations of the bounded field. It then progresses to the next 'round' whereby the centre 'combination' of this set of bounds (in this case, the original field boundary) is tuned – this is referred to as the 'centre combination'.

Unlike previous generations of tuners, the combinations haven't been generated in advance using set values of every hyperparameter that the user wants to be tested, rather each new centre is generated on the fly by taking the mean value of the previous bounds for every hyperparameter. In the case where the hyperparameter has discrete values, it splits the original field into many (the number being the same as its number of discrete values) other fields with one less dimension, where in those fields the values for this specific parameter is now constant (of course, for multiple discrete hyperparameters the field will be split into n*m smaller fields, where n and m are the numbers of values in the two discrete hyperparameters respectively; the new fields will have k less dimensions than the original field, with k being the number of discrete hyperparameters that are being tuned). In the case where a hyperparameter is semi-continuous (i.e. ordinal values), its median rank value will be attempted to be taken, but if after several rounds there is only one value left in the semi-continuous/ordinal hyperparameter, it is treated as discrete.

Users need to specify whether a variable is categorical (discrete) after they have entered bounds.

At every 'round' except the first round, GuangAn use the boundary combinations to fit a linear regression model, and if the observed centre combination's validation score is not within \pm 0.005 of the predicted centre combination score, then it continues to create new boundaries using the current boundary and the centre that has just been tuned, and repeat the process at the start of the paragraph. If it is within \pm 0.005, it is considered a 'fit' and this particular boundary does not need to be further divide-and-conquered. Do keep in mind that many, many boundaries will be created as the divide and conquer process evolves.

At the end of each round, only the new boundaries that were derived from the centre combinations with the top $max(64, 2^d)$ validation scores are proceeded into the next round, as part of a pruning mechanism. This is necessary or else the number of new boundaries that are

generated will expand exponentially as the 'rounds' grows higher, and most of the combinations being pursued are stuck at mediocre validation score regions.

The algorithm has a 'wall-time'-like mechanism in that if all continuous hyperparameter's lower bounds and upper bounds in a new boundary is smaller than 0.1, then that new boundary will not be pursued as it is considered too fined grained and not worthy of being investigated. Note that despite this, this algorithm will still reach into finer values than those of lower generation (i.e. n_estimators down to unit values, instead of coarse 3, 6, 9, 12, 24, 48 etc; subsample values finer than 0.1 level).

Note also that values that are trained as exponential values in lower generation algorithms are changed considered by their log(10) values, so for a fairer mean-value when tuning.

Users need to specify whether a variable needs to undergo transformation after they have set bounds.

If the observed 'centre combination' produces a negative validation score after the third 'round', it is automatically discarded as very likely the algorithm has searched into an area of the field with terrible combinations.

When the initial round by round 'guidance' stage has terminated (i.e. no new boundaries need to be tested), the boundary containing the maximum observed validation score will undergo a further round (just by itself), to ensure that there is no further maximum within the boundary. If a new maximum is found, then the 'boundaries containing the maximum' will be adjusted, and go through the 'cruise' process again, until the maximum observed validation score is unchanged after a round.

Class

Class	<u>Purpose</u>
GuangAn	Object that performs divide and conquer
	tuning

Methods:

<u>Methods</u>	<u>Purpose</u>	
GuangAn()	Initialisation	
<pre>read_in_data(train_x, train_y, val_x, val_y, test_x, test_y)</pre>	Read in Train Test Split data	
	Parameters:	
	train_data – pd.DataFrame	
	val_data - pd.DataFrame	
	test_data - pd.DataFrame	
read_in_model(model, type)	Read in the underlying model class that we	
	want to tune to get optimal parameters for	
	Parameters: model – any model class that allows .fit() and .predict()	
	type – str – either "Classification" or "Regression"	
set_hyperparameters(parameter_ranges_o	Read in the different values of each	
rig)	hyperparameters we want to try. Function	
	will automatically generate each combination	
	Parameters: parameter_ranges_orig - dict of str:list/str:set/str:dict- str is hyperparameter name (strictly as defined in model class), and list has 2 values in ascending order denoting bounds; set contains values in ascending order.	

set_non_tuneable_hyperparameters(non_t	Reads in values for non-tuneable	
uneable_hyperparameter_choice)	hyperparameters (i.e. doesn't need to clog up	
	the tuning output csv)	
	Parameters:	
	non_tuneable_hyperparameter_choices - dict	
	of str:int	
read_in_transform(transform_update)	Specifies which tuneable hyperparameter	
	values should be log10 transformed during	
	tuning.	
	Parameters:	
	transform_update - dict of str:str - key str is	
	hyperparameter name (strictly as defined in	
	model class), and value str is type of	
	transform	
	*currently only support '10^' which	
	represents log10 transformation	
read_in_categorical(categorical_update	Specifies which tuneable hyperparameter	
)	values should be considered categorical	
	during tuning	
	Parameters:	
	categorical_update – list of strs - str is	
	hyperparameter name (strictly as defined in	
	model class)	
set_features(ningxiang_output)	Reads in feature combinations for tuning	
	Parameters:	
	ningxiang_output – dict of tuple:float	
set_tuning_result_saving_address(addre	Set saving address for tuning output csv	
ss)		

	Parameters: address – str – does not need to include '.csv'	
set_best_model_saving_address(address)	Set best model saving address	
	Parameters:	
	address – str – does not need to include	
	'.pickle'	
tune()	Begin tuning process	
read_in_tuning_result_df(df_address,	Read in existing dictionary from .pickle	
object_address)	consisting of tuning result.	
	Automatically populates result array and	
	checked array if csv columns match	
	parameter choices	
	*even though users are reading in a pickled	
	dictionary, the original method name was	
	still retained in line with original JiaXing	
	methods.	
	Parameters:	
	df_address - str - include '.csv'	
	object_address – str – include '.pickle	
<pre>view_best_combo_and_score()</pre>	View the current best combination and its	
	validation score	

Objects:

train_y S val_x	DataFrame Series DataFrame Series DataFrame Series DataFrame	
val_x [val_y [test_x [DataFrame Series DataFrame	
val_y S test_x I	Series DataFrame	
test_x	DataFrame
